1 Introduction

This list of problems arose as a collaborative effort among the participants of the *Arbeitsgemeinschaft* on Mathematical Quasicrystals, which was held at the Mathematisches Forschungsinstitut Oberwolfach in October 2015. The purpose of our meeting was to bring together researchers from a variety of disciplines, with a common goal of understanding different viewpoints and approaches surrounding the theory of mathematical quasicrystals. The problems below reflect this goal and this diversity and we hope that they will motivate further cross-disciplinary research and lead to new advances in our overall vision of this rapidly developing field.

Most of the technical terms used herein are fairly common in the literature surrounding this subject. When in doubt concerning definitions, the reader may wish to

consult [Baake and Grimm \(2013\)](#) or [Sadun \(2008\)](#), as well as the references provided with the relevant problem. Here we list some less common terms and abbreviations used below:

- (i) Two point sets in \mathbb{R}^d are *bounded displacement equivalent* (abbreviated BD) if there is a bijection between them which moves every point by at most some finite amount.
- (ii) Two point sets in \mathbb{R}^d are *bi-Lipschitz equivalent* (abbreviated BL) if there is a bi-Lipschitz bijection between them.
- (iii) A pattern $Y \subseteq \mathbb{R}^d$ is *linearly repetitive* (abbreviated LR) if there exists a constant $C > 0$ such that, for every $r \geq 1$, every patch of size r which occurs anywhere in Y , occurs in every ball or radius Cr in \mathbb{R}^d .
- (iv) The abbreviation MLD stands for *mutually locally derivable*, as defined in [Baake and Grimm \(2013, Section 5.2\)](#).

2 Problems

2.1 D. Damanik: Quantum Mechanics and Quasicrystals

A Schrödinger equation associated with a Schrödinger operator H can be used to model how well quantum wave packets travel in a quasicrystal—see [Damanik and Tcheremchantsev \(2010\)](#) for details. A key step in the determination of the large time behaviour of solutions to this equation is the understanding of the properties of the spectrum of H and of the corresponding spectrum measures. Theorem 2.1.1 below illustrates the kind of properties that are of interest. Before stating it, we introduce some notation and some definitions.

Given a finite alphabet \mathcal{A} , let $\mathbf{x} \in \mathcal{A}^{\mathbb{N}}$ (resp. $\mathbf{x} \in \mathcal{A}^{\mathbb{Z}}$) be a single sided (resp. a double sided) recurrent sequence over \mathcal{A} . The complexity of \mathbf{x} is defined for each integer $n \geq 1$ as

$$p(n) := \#\{x_m \dots x_{m+n-1} : m \in \mathbb{Z}\}$$

if the sequence is double sided. If it is single sided, the complexity is defined in the same way upon restricting m to the set of positive integers. When \mathbf{x} is aperiodic (i.e. not ultimately periodic), it is easily seen that $p(n) \geq n + 1$ for all $n \geq 1$. The sequence \mathbf{x} is Sturmian if it is aperiodic and if it has minimal complexity; that is, if $p(n) = n + 1$ for all $n \geq 1$. This definition implies that the alphabet defining a Sturmian sequence contains exactly two letters which may be denoted without loss of generality by 0 and 1. One can then show ([Lothaire 2002](#)) that a double sided (resp. single sided) Sturmian sequence is exactly of one of the following forms: for all $m \in \mathbb{Z}$ (resp. for all $m \in \mathbb{N}$),

$$x_m := \chi_{[1-\alpha; 1)}(\{m\alpha + \theta\}) \quad \text{or} \quad x_m := \chi_{(1-\alpha; 1]}(\{m\alpha + \theta\}).$$

Here, $\{x\}$ denotes the fractional part of $x \in \mathbb{R}$, χ_E the characteristic function of a set $E \subset \mathbb{R}$ and α and θ are two real numbers such that $\alpha \in \mathbb{R} \setminus \mathbb{Q}$ and $\theta \notin \alpha\mathbb{Z} + \mathbb{Z}$.

The following result is established in [Bellissard et al. \(1989\)](#) and [Damanik et al. \(2000\)](#).

Theorem 2.1.1 *Let $\lambda \in \mathbb{C}$ and let $\mathbf{x} \in \{0, 1\}^{\mathbb{Z}}$ be a Sturmian sequence. Denote by H the Schrödinger operator defined in the space $l^2(\mathbb{Z})$ as follows: given $\psi \in l^2(\mathbb{Z})$ and $m \in \mathbb{Z}$, let*

$$[H\psi](m) := \psi(m + 1) + \psi(m - 1) + \lambda \cdot x_m \cdot \psi(m).$$

Then, the spectrum $\sigma(H)$ of the operator H is a zero Lebesgue measure Cantor set. Furthermore, all spectral measures are singular continuous.

Another measure of the complexity of a sequence has been introduced by [Kamae and Zamboni \(2002a, b\)](#). It is defined as follows (with the natural modification if the sequence is single sided): for $n \geq 1$,

$$p^*(n) := \sup_{0=\tau(0)<\dots<\tau(n-1)} \# \{x_{m+\tau(0)} \cdots x_{m+\tau(n-1)} : m \in \mathbb{Z}\},$$

where $\tau(0), \dots, \tau(n - 1)$ are integers. It is not difficult to see that if \mathbf{x} is an aperiodic sequence, then $p^*(n) \geq 2n$ for all $n \geq 1$. The sequence \mathbf{x} is *pattern Sturmian* if $p^*(n) = 2n$ for all $n \geq 1$. Note that a Sturmian sequence is necessarily pattern Sturmian. The converse inclusion, however, does not hold.

Problem 2.1.1 Determine all single sided (resp. double sided) sequences that are pattern Sturmian.

With respect to the properties of the Schrödinger operator introduced in [Theorem 2.1.1](#) above, one can expect the following:

Conjecture 2.1.1 *Theorem 2.1.1 holds if \mathbf{x} is a pattern Sturmian sequence.*

The spectrum of Schrödinger operators associated with quasicrystal models in higher dimensions is not well understood. Consider for example the Penrose tiling and the corresponding graph (V, E) , where V is the vertex set and E the set of edges. Define the operator H in the space $l^2(V)$ as follows: for any $\psi \in l^2(V)$ and any $v \in V$, let

$$[H\psi](v) := \sum_{w:(v,w) \in E} (\psi(w) - \psi(v)).$$

Problem 2.1.2 Determine the spectrum $\sigma(H)$ of the operator defined above.

Another example of a two dimensional problem arises when considering a two dimensional potential V that can be written as a sum of two one dimensional potentials $s_1^{\lambda_1}$ and $s_2^{\lambda_2}$. Here, $\lambda_1, \lambda_2 \in \mathbb{C}$ and, for $j \in \{1, 2\}$ and $k \in \mathbb{Z}$,

$$s_j^{\lambda_j}(k) := \lambda_j \cdot \chi_{[1-\gamma, 1)}(\{k\gamma\})$$

with $\gamma = \frac{\sqrt{5}-1}{2}$. Thus, for any $m, n \in \mathbb{Z}$,

$$V(m, n) := s_1^{\lambda_1}(m) + s_2^{\lambda_2}(n).$$

The corresponding Schrödinger operator H in the space $l^2(\mathbb{Z}^2)$ is defined as follows: for $\psi \in l^2(\mathbb{Z})$ and $(m, n) \in \mathbb{Z}^2$,

$$\begin{aligned} [H\psi](m, n) := & \psi(m+1, n) + \psi(m-1, n) + \psi(m, n+1) \\ & + \psi(m, n-1) + V(m, n) \cdot \psi(m, n). \end{aligned}$$

The spectrum of this operator is expected to exhibit a very particular structure for some values of the parameters λ_1 and λ_2 :

Conjecture 2.1.2 *There exist values of λ_1 and λ_2 such that the spectrum $\sigma(H)$ of H is a Cantorval; that is, the spectrum is the closure of its interior and no connected component is isolated.*

For more details on the concept of Cantorval, see [Mendes and Oliveira \(1994\)](#). With obvious modifications, Conjecture 2.1.2 is expected to be true in higher dimensions as well.

2.2 F. Gähler: The Pisot Substitution Conjecture

One of the long-standing open problems in the field of mathematical quasicrystals is to determine which tiling dynamical systems (or Delone dynamical systems) have a pure point dynamical spectrum and thus a pure point diffraction pattern. For cut-and-project sets and tilings, this is the case by construction, but for inflation tilings the situation is not as clear. It is known ([Solomyak 1997](#)) that a self-similar inflation tiling has a non-trivial pure point component in its spectrum if, and only if, the scaling factor of the inflation is a Pisot number λ ; that is, a real algebraic integer $\lambda > 1$ all of whose conjugates are strictly smaller than one in modulus. This does not mean, however, that the spectrum is pure point. There is an algorithm ([Sirvent and Solomyak 2002](#); [Solomyak 1997](#)) that enables one to check whether a given tiling has pure point spectrum. Nevertheless, simple criteria that are easy to check or known to be true for whole classes of tilings are missing.

The *Pisot Substitution Conjecture* (see also the recent review [Akiyama et al. 2015](#)) states the following:

Conjecture 2.2.1 (Pisot substitution conjecture) *A one-dimensional self-similar inflation tiling with Pisot scaling factor λ has pure point spectrum if its abelianisation matrix (i.e. its substitution matrix) M has an irreducible characteristic polynomial; that is, if the algebraic degree of λ equals the dimension of M (or the number of tile types).*

Often, the additional assumption that M is unimodular is made so that λ is a unit in the ring $\mathbb{Z}[\lambda]$. So far, this has not really helped to prove the conjecture.

Extensive computer search (Akiyama et al. 2014) has failed to produce a counterexample but a general proof is also missing. There are some partial results. The conjecture is known to be true in the two tile case (λ a quadratic irrational) (Hollander and Solomyak 2003). Also, it has been recently been proved for the class of inflation rules which are injective on the first tile and constant on the last tile (Barge 2016) and also for β -substitutions (Barge 2015b) (which do not generally satisfy the conditions of the Pisot Substitution Conjecture).

One problem with the Pisot Substitution Conjecture is that the irreducibility of the characteristic polynomial of M is not invariant under topological conjugacies, whereas the spectral type of the dynamical system is. This has led to the statement of Pisot type conjectures with additional assumptions of a topological nature. The *Homological Pisot Conjecture* (Barge et al. 2012) is in this vein:

Conjecture 2.2.2 (Homological Pisot Conjecture) *A one-dimensional, unimodular Pisot inflation tiling has pure point spectrum if its first rational Čech cohomology group has rank equal to the algebraic degree of λ .*

This was later extended to the non-unimodular case in the form of the *Coincidence Rank Conjecture* (Barge 2015a):

Conjecture 2.2.3 (Coincidence Rank Conjecture) *The coincidence rank of a one-dimensional Pisot inflation tiling must divide the algebraic norm of λ .*

The coincidence rank is the multiplicity (almost everywhere) of the factor map to the maximal equicontinuous factor of the tiling dynamical system. It must be one for pure point spectrum.

2.3 U. Grimm: Diffraction of a Pinwheel Tiling

We first briefly describe the construction of a Pinwheel Tiling following Conway and Radin—see Conway and Radin (1998) and Radin (1994) for further details and Moustafa (2010) for some of its properties.

Let \mathcal{T} be a right triangle with side lengths 1, 2 and $\sqrt{5}$. As noticed by Conway, \mathcal{T} can be divided into five isometric copies of its image by a dilation of factor $1/\sqrt{5}$ —see Fig. 1.¹ A Pinwheel Tiling is then defined as a tiling of the plane whose tiles are isometric copies of \mathcal{T} , in which a tile may intersect another tile only either on a whole side or on half the length 2 side, and such that the following property holds: the tiles of any Pinwheel Tiling can be grouped in sets of five into homothetic tiles, so that these homothetic tiles form (up to rescaling) a new Pinwheel Tiling.

There are uncountably many Pinwheel Tilings. See Fig. 2 below for an example.

All Pinwheel Tilings are locally indistinguishable (i.e. any cluster which occurs in one Pinwheel Tiling, occurs in all such tilings) and share the property that tiles appear in infinitely many orientations. Choose a reference point (a natural choice is the point at coordinates $(1/2, 1/2)$ with respect to the vertex point at the right-angled corner of the triangular tile) and consider a uniform Dirac comb obtained by placing a point

¹ Figures 1 and 2 are taken from Wikipedia.

Fig. 1 Conway triangle decomposition into homothetic smaller triangles

Fig. 2 A Pinwheel tiling

measure at each reference point. The diffraction measure is the Fourier transform of the autocorrelation and is a well-defined positive measure. It is known that this measure has circular symmetry (Moody et al. 2006) and, as a consequence, the only pure point part of it is the trivial point measure at the origin, which is related to the density (equal to one in this case). Apart from this point measure, the diffraction measure is continuous. However, note that a measure concentrated on ‘sharp rings’ (so that the measure is ‘pure point in the radial direction’) is a singular continuous measure in the plane as well.

There are arguments that support the existence of such ‘sharp rings’ in the diffraction measure of the pinwheel tiling (Baake et al. 2007) similarly to what one would observe for a rotation-averaged square lattice arrangement of point masses. Numerical investigations also indicate the presence of additional components which might be absolutely continuous (Baake et al. 2007; Grimm and Deng 2011). However, none of these properties has yet been proved.

Problem 2.3.1 Determine the position of sharp rings in the diffraction measure of a Pinwheel Tiling and their intensity.

Problem 2.3.2 Does the diffraction measure of the Pinwheel Tiling contain an absolutely continuous component?

2.4 A. Haynes: Gaps Problems

Let $\alpha, \beta \in \mathbb{R}$ be such that $1, \alpha$ and β are \mathbb{Q} -linearly independent. Let $Y(\alpha, \beta)$ be a canonical cut-and-project set (this concept is defined in Haynes et al. 2016a) formed using the subspace

$$E(\alpha, \beta) := \{(x, y, \alpha x + \beta y) : x, y \in \mathbb{R}\} \subset \mathbb{R}^3.$$

Given a shape $\Omega \subset E(\alpha, \beta)$, let $\xi_{(\alpha, \beta)}(\Omega)$ denote the set of different frequencies of patches of shape Ω in $Y(\alpha, \beta)$ which occur in $E(\alpha, \beta)$. Precise definitions of these terms are given in [Haynes et al. \(2016c\)](#) and here we are considering “type 2 patches”.

Let $M, N \in \mathbb{N}$ and

$$S_{(\alpha, \beta)}(M, N) := \{m\alpha + n\beta : 0 \leq m < M, 0 \leq n < N\},$$

where $\{x\}$ denotes the fractional part of $x \in \mathbb{R}$. Depending on the choice of the shape Ω , the cardinality of $\xi_{(\alpha, \beta)}(\Omega)$ is closely related to the number $G_{(\alpha, \beta)}(M, N)$ of distinct lengths of the component intervals of $\mathbb{T} \setminus S_{(\alpha, \beta)}(M, N)$ for specific choices of M and N (here, $\mathbb{T} = \mathbb{R}/\mathbb{Z}$ denotes the one-dimensional torus). For instance, the number of different frequencies for a two-to-one cut-and-project set when the window is an interval is at most 3. This is just another formulation of the Three Distance (or Steinhaus) Theorem and amounts to saying that $G_{(\alpha, \beta)}(1, N) \leq 3$ for any $N \geq 1$.

Problem 2.4.1 Is there a choice of α and β as above such that

$$\sup_{\Omega \in \mathcal{S}} \#\xi_{(\alpha, \beta)}(\Omega) = +\infty, \tag{1}$$

where \mathcal{S} denotes the collection of all aligned squares?

The precise definition of an aligned square (resp. of an aligned rectangle) can be found in [Haynes et al. \(2016b\)](#).

It can be shown ([Haynes et al. 2016c](#)) that (1) implies that $\sup_{N \in \mathbb{N}} G_{(\alpha, \beta)}(N, N) = +\infty$. It was conjectured by Erdős ([Geelen and Simpson 1993](#)) that the latter equation should hold whenever $1, \alpha$ and β are \mathbb{Q} -linearly independent. This conjecture was disproved in [Bleher et al. \(2012\)](#), where it was established that the set of (α, β) for which $\sup_{N \in \mathbb{N}} G_{(\alpha, \beta)}(N, N) < +\infty$, although of zero Lebesgue measure, has full Hausdorff dimension. It is an open problem to determine whether there exists a pair (α, β) such that $\sup_{N \in \mathbb{N}} G_{(\alpha, \beta)}(N, N) = +\infty$.

The following is a seemingly easier version of the previous problem.

Problem 2.4.2 Is there a choice of α and β as above such that

$$\sup_{\Omega \in \mathcal{R}} \#\xi_{(\alpha, \beta)}(\Omega) = +\infty, \tag{2}$$

where \mathcal{R} denotes the collection of aligned rectangles?

There is currently no known example of a pair (α, β) for which (2) holds. Using the arguments in [Haynes et al. \(2016b, c\)](#), it can be shown that any such pair satisfies the equation

$$\liminf_{n \rightarrow \infty} n \|n\alpha\| \|n\beta\| = 0; \tag{3}$$

that is, any such pair satisfies the Littlewood Conjecture (here, $\|x\|$ denotes the distance from $x \in \mathbb{R}$ to a nearest integer). Whether the converse holds is an open problem:

Problem 2.4.3 Given $(\alpha, \beta) \in \mathbb{R}^2$ such that $1, \alpha$ and β are \mathbb{Q} -linearly independent, does (3) imply (2)?

2.5 A. Julien: Relationship Between Complexity and Cohomology

Consider a tiling and the corresponding tiling space Ω in dimension $d \geq 1$. In the case of a word w over a finite alphabet (the tiling is then one-dimensional), the complexity function $n \mapsto p(n)$ corresponding to w counts the number of subwords of w of length n . In higher dimensions, the complexity function of a tiling counts in an analogous way the number of patches of radius n (up to translation)—see [Lagarias and Pleasants \(2003\)](#) for details.

In the case of a canonical (in particular, irrational and aperiodic) cut-and-project tiling, it is known ([Julien 2010](#), Theorem 5.1) that the complexity function grows like $O(n^d)$ if, and only if, the groups of cohomology over \mathbb{Q} of the tiling space are finitely generated. In other words, with usual notation,

$$p(n) = O(n^d) \iff \text{rk}(H^*(\Omega, \mathbb{Q})) < \infty.$$

The situation is not as well understood in the non-cut-and-project setup. For instance, there exist tilings in any dimension $d \geq 1$ such that the corresponding tiling spaces have finitely generated groups of cohomology over the rationals whereas their complexity function grows faster than any polynomial—see, e.g., [Julien \(2010, Proposition 6.20\)](#). In dimension $d = 1$ however, the converse can be settled in the affirmative ([Julien 2010, Proposition 6.7](#)): if $p(n) = O(n)$, then $\text{rk}(H^1(\Omega, \mathbb{Q})) < \infty$. The following problem is concerned with a generalization of this result in higher dimensions:

Problem 2.5.1 With the same notation, is it the case that for an aperiodic, repetitive tiling of dimension d , if $p(n) = O(n^d)$, then $\text{rk}(H^*(\Omega, \mathbb{Q})) < \infty$?

Note that the result fails already in dimension one if one considers cohomologies over \mathbb{Z} rather than over \mathbb{Q} . Indeed, the substitution defining the Thue–Morse sequence is primitive and therefore ([Queffélec 2010](#)) the corresponding complexity function is bounded above by a linear function. Besides, one can show ([Anderson and Putnam 1998](#)) that

$$H^1(\Omega_{TM}, \mathbb{Z}) \simeq \mathbb{Z} \left[\frac{1}{2} \right] \oplus \mathbb{Z}.$$

In particular, $H^1(\Omega_{TM}, \mathbb{Z})$ is not finitely generated over \mathbb{Z} .

2.6 A. Navas: A Conjecture on Delone Sets BL to Lattices (After P. Alestalo, D. A. Trotsenko and J. Väisälä)

[Burago and Kleiner \(2002\)](#) on the one hand and [McMullen \(1998\)](#) on the other proved independently that there exist Delone sets in any dimension which are not BL to any

lattice. The following problem, raised in Alestalo et al. (1993), is concerned with the case when a Delone set is BL to a lattice in the plane. As any two lattices are BL, it is enough to consider the case of \mathbb{Z}^2 .

Problem 2.6.1 Let $\mathcal{D} \subset \mathbb{R}^2$ be a Delone set BL to \mathbb{Z}^2 . Does there exist a bi-Lipschitz map $L : \mathbb{R}^2 \mapsto \mathbb{R}^2$ such that $L(\mathcal{D}) = \mathbb{Z}^2$?

In this direction, it has been shown (Navas 2016) that the conclusion of Problem 2.6.1 is valid under the assumption of linear repetitivity (LR) or under the assumption of Burago–Kleiner (BK). Both of these conditions imply that a Delone set is BL to a lattice. The reader is referred to Burago and Kleiner (1998) for an actual definition of the BK condition, which is technical. It is concerned with the speed of convergence of the number of points of a Delone set inside larger and larger balls.

2.7 L. Sadun

2.7.1 Properties of Patterns and Properties of Tiling Spaces

There are two very different approaches to tiling theory. A first approach focuses on questions about specific patterns such as: are they BD or BL to a lattice? Are they LR? Do they have a pure point diffraction spectrum? Do they have the Meyer property?

A second approach focuses on properties of tiling *spaces* such as: what is the cohomology? What is the maximal equicontinuous torus? What is the dynamical spectrum? From a dynamical perspective, tilings that are MLD or that give topologically conjugate tiling spaces are essentially the same. In some settings, even homeomorphic tilings are considered “the same”.

Unfortunately, the answers to the first set of questions are not generally preserved inside classes of equivalence of tiling spaces. A natural question is thus to ask whether one can reconcile the two approaches. One strategy to answer this question is to consider a strong version of the BD or BL or LR or . . . properties.

Problem 2.7.1 Classify tilings with such a property that any other tiling MLD (or topologically conjugate, or homeomorphic) to it also has that property.

A more ambitious (and open-ended) challenge is the following:

Problem 2.7.2 Develop and study new geometric properties, analogous but not identical to BD, BL, etc., that *are* invariant under MLD, topological conjugacy, or homeomorphism.

2.7.2 Modelling Physical Phenomena with Quasicrystals (After J. Miękisz)

Many physical phenomena are characterized by short range properties. Examples include thermal stability (temperature is stable under local perturbation), the interactions between two atoms close to each other or else the short range interaction when studying chemical potential. Any quasicrystal model used to describe such phenomena should take into account these local properties.

With this in view, [Miękisz \(1998\)](#) labelled two properties that should be satisfied by a local matching rule used to define a tiling:

- (A) Given a tile t and a region \mathcal{R} of the tiling space made of a finite union of tiles, define the discrepancy $D_t(\mathcal{R})$ of the tile t in \mathcal{R} as

$$D_t(\mathcal{R}) := |N_t(\mathcal{R}) - d(t) \cdot \text{vol}(\mathcal{R})|.$$

Here, $N_t(\mathcal{R})$ stands for the cardinality of the number of tiles t in the region \mathcal{R} and $d(t)$ for the density of the tile t . The first condition imposed on the tiling is that of “low fluctuation”; that is, that there exists a constant c_t depending only on the tile t such that

$$D_t(\mathcal{R}) \leq c_t \cdot |\partial\mathcal{R}|, \tag{4}$$

where $|\partial\mathcal{R}|$ is the measure of the boundary $\partial\mathcal{R}$ of \mathcal{R} . It should be noted that, up to the constant c_t , one cannot expect a bound better than the right-hand side of (4) for the discrepancy $D_t(\mathcal{R})$ —see [Miękisz \(1999\)](#) for details.

- (B) The second condition is that property (A) should also hold for any pattern or patch satisfying the given matching rule.

Problem 2.7.3 Find a set of matching rules in dimension 2 and/or 3 that meet both condition (A) and condition (B).

Regarding condition (A), if the system is not uniquely ergodic, then the fluctuations grow like volume (rather than perimeter) and there is no hope to solving the problem. In particular, whenever the problem is relevant, density is well-defined. Another approach, which does not involve defining density at all, is to look at the difference in population between two different patches of approximately the same volume and to ask whether that difference is bounded by the perimeter(s) and the difference in the volumes. Regarding condition (B), if a patch violates the matching rules at a small set of tiles, one can get another patch that does not violate the rules by simply deleting that small set. This is the main difficulty underlying [Problem 2.7.3](#).

The following statement can be seen as a first step to the solution of [Problem 2.7.3](#).

Problem 2.7.4 Find a set of matching rules in dimension 2 satisfying condition (A) only.

The contributor is able to produce an example based on the ideas developed in [Miękisz \(1999\)](#) solving the analogue of [Problem 2.7.4](#) in dimension 3. In dimension 2 however, all known examples of matching rules (e.g., that corresponding to the Penrose tiling) have a discrepancy growing like $O(|\partial\mathcal{R}| \cdot \log |\partial\mathcal{R}|)$.

2.8 B. Weiss

2.8.1 On a Problem of J. Marklof

Let $d \geq 1$ be an integer. Denote by $\mathbf{CI}(\mathbb{R}^d)$ the set of all closed subsets of \mathbb{R}^d with respect to the Chabauty–Fell topology ([de la Harpe 2016](#)). Thus, $\mathbf{CI}(\mathbb{R}^d)$ is a compact metric space and any group acting on \mathbb{R}^d acts on it by transporting closed sets.

Let $SL_d(\mathbb{R})$ denote the group of matrices in dimension d with determinant one, viz. the group of all volume and orientation preserving linear transformations in \mathbb{R}^d . Let $ASL_d(\mathbb{R})$ denote the affine group in \mathbb{R}^d , viz. the group of all orientation and volume preserving affine maps in \mathbb{R}^d .

Problem 2.8.1 (J. Marklof) Determine all $SL_d(\mathbb{R})$ -invariant Borel probability measures on $\mathbf{CI}(\mathbb{R}^d)$ and similarly for the $ASL_d(\mathbb{R})$ action.

Examples of such measures include the Dirac masses at \emptyset and at \mathbb{R}^d , the measures derived from a Poisson process, those naturally equipping the space of grids and translated lattices and also those equipping the space of cut-and-project sets.

This problem is motivated by questions in mathematical physics—see [Marklof and Strömbergsson \(2014\)](#) for some recent work and [Marklof \(2015\)](#) for a survey. A topological analogue of this problem was resolved in [Solan et al. \(2015\)](#): it was proved that the only $ASL_d(\mathbb{R})$ -minimal sets are the fixed points \emptyset, \mathbb{R}^d (recall that a minimal set is a closed invariant set with no proper closed invariant subsets).

2.8.2 A “Folklore” Problem Concerning the Properties of Cut-and-Project Sets

In relation with [Problem 2.6.1](#) above, there is a well-known open problem in the theory of aperiodic tilings which essentially asks whether there exists a cut-and-project set which is not BL to a lattice. The problem can be formulated more rigorously in the following way:

Problem 2.8.2 Let $E \subset \mathbb{R}^k$ be a totally irrational subspace of dimension $d \geq 1$, and let Y be a cut-and-project set obtained from E using a bounded window \mathcal{W} with non-empty interior and with the property that the $(k - d)$ -dimensional Lebesgue measure of $\partial\mathcal{W}$ is zero. Is such a set Y always BL to a lattice in E ?

In [Burago and Kleiner \(2002\)](#), it was shown that when $k = 3, d = 2$ and when \mathcal{W} is an interval, then the set Y is BL to a lattice provided that E satisfies a mild Diophantine condition. In [Haynes et al. \(2014\)](#), a more general result is proved, which applies for all choices of k and d with a Diophantine hypothesis on E , and for all windows \mathcal{W} with the property that the upper Minkowski dimension of $\partial\mathcal{W}$ is less than $k - d$. Further results related to this problem can be found in [Haynes \(2016\)](#) and [Haynes and Koivusalo \(2016\)](#).

It should be noted that if the window in the above problem is only required to be bounded, then it is not difficult (regardless of what E is) to choose \mathcal{W} so that the resulting set Y is not BL to a lattice. To see how to do this, suppose that $k = 3$ and $d = 2$ and assume without loss of generality that $E + e_3 = \mathbb{R}^3$, where e_3 denotes a standard basis vector in \mathbb{R}^3 . Let $F = \mathbb{R}e_3$ and let ρ_E and ρ_F be the projections from \mathbb{R}^3 onto E and F with respect to the decomposition $\mathbb{R}^3 = E + F$. Let $S' \subseteq \mathbb{R}^3$ be defined by

$$S' = \rho_F^{-1}(\{te^3 : 0 \leq t < 1\}).$$

Start with a Delone set Y' in $\langle e_1, e_2 \rangle_{\mathbb{R}}$ which is a subset of $\langle e_1, e_2 \rangle_{\mathbb{Z}}$, but which is not BL to a lattice in $\langle e_1, e_2 \rangle_{\mathbb{R}}$ (such sets can be produced, for example, by the construction

given in Cortez and Navas 2016). Then, taking the window to be the bounded set given by

$$\mathcal{W} = \rho_F(\{n \in \mathbb{Z}^3 \cap \mathcal{S}' : \rho_E(n) \in \rho_E(Y')\}),$$

it is clear that the corresponding cut-and-project set Y is not BL to a lattice.

Acknowledgments The author would like to thank all the contributors (viz. David Damanik, Franz Gähler, Uwe Grimm, Alan Haynes, Antoine Julien, Andrés Navas, Lorenzo Sadun and Barak Weiss) for providing such interesting problems and for their careful reading of a preliminary draft of the paper. He would in particular like to thank Prof. Barak Weiss for suggesting the idea of this problem set and for his help during its elaboration. The introduction was written up by Dr. Alan Haynes. The author's work was supported by EPSRC Programme Grant EP/J018260/1.
